### ABSTRACT

Increases in extreme weather events associated with climate change have the potential to put currently healthy forests at risk. One option to minimize this risk is the application of forest management measures aimed at generating species mixtures predicted to be more resilient to these threats. In order to apply such measures appropriately, forest managers need up-to-date, accurate and consistent forest maps at relatively fine spatial resolutions. Cost efficiency is a major factor when creating such maps. Taking European spruce (*Picea abies*) and Scots pine (*Pinus sylvestris*) as an example, this paper describes an innovative approach for mapping two tree species using a combination of commercial very high resolution WorldView-2 (WV2) images and Landsat time series data. As a first step, this study used a supervised object-based classification of WV2 images covering relatively small test sites distributed across the region of interest. Using these classification maps as training data, wall-to-wall mapping of fractional coverages of *spruce* and *pine* was achieved using multi-temporal Landsat data and Random Forests (RF) regression. The method was applied for the entire state of Bavaria (Germany), which comprises a total forested area of approximately 26,000 km<sup>2</sup>. As applied here, this two-step approach yields consistent and accurate maps of fractional tree cover estimates with a spatial resolution of 1 ha. Independent validation of the fractional cover estimates using 3780 reference samples collected through visual interpretation of orthophotos produced root-mean-square errors (RMSE) of 11% (for *spruce*) and 14% (for *pine*) with almost no bias, and R<sup>2</sup> values of 0.74 and 0.79 for *spruce* and *pine*, respectively. The majority of the validation samples (75% (*spruce*) and 84% (*pine*)) were modeled within the assumed uncertainty of ± 15% of the reference sample. Accuracies were significantly better compared to those achieved using a single-step classification of Landsat time series data at the pixel level (30 m), because the two-step approach better captures regional variation in the spectral signatures of target classes. Moreover, the increased number of available reference cells mitigates the impact of occasional errors in the reference data set. This two-step approach has great potential for cost-effective operational mapping of dominant forest types over large areas.

### 1. Introduction

Climate change is expected to have an important influence on future growing conditions that will likely have a great impact on tree species. Depending on the location, some tree species will benefit, for example, from increasing temperatures and thus, extended vegetation periods. However, at other locations, increased temperatures are likely to lead to water stress, and hence, greater vulnerability of some tree species to abiotic and biotic disturbances (Lindner et al., 2010). In Central Europe,

several coniferous tree species are of particular concern: the vulnerability of tree species such as European spruce and Scots pine is particularly high in areas where they are planted outside their natural ranges (Kölling et al., 2009a; Lindner et al., 2014; Seidl et al., 2017). As both species are of high economic importance for the European forest sector, targeted forest management is necessary to minimize economic losses. In order to identify areas of increased risk, Kölling et al. (2009b) produced risk maps for different tree species based on different climate scenarios for Bavaria, Germany. Identification of particularly

vulnerable forest stands at a fine spatial resolution is a logical follow-up step to ensure efficient planning of silvicultural activities. Therefore, risk maps depicting (future) growing conditions must be combined with precise species distribution information. Unfortunately, data of sufficient detail for tree species distribution at a suitable spatial resolution (i.e. percentage cover in 1 ha cells) is still missing.

Long-established forest inventories in Europe provide important data about forest composition based on precise information obtained from field plots where repeated periodic terrestrial observations are made. However, the data collected is inappropriate for providing detailed enough spatial information at the local to regional levels to guide forest management decisions of the scale required to meet the challenges brought about by climate change. In order to extrapolate information obtained from these spatially specific plots to a wider area, spatial interpolation methods such as kriging have been employed in the past. Such procedures permit production of distribution maps of tree species based on inventory data. The European Forest Institute (EFI), for example, has produced Europe-wide maps using data mainly obtained from national forest inventories (Brus et al., 2012). These data provide a good overview of the general distribution of the species, but at 1 km spatial resolution, these maps still lack sufficient spatial detail, particularly for less abundant species. The tree species distribution maps available from the Forest Information System for Europe (JRC, 2017) are another example of a data set with similar limitations.

Earth Observation (EO) derived data products covering large areas usually only provide information on the presence or absence of forests or on percent tree cover. Prominent examples of such products are the global forest cover and forest cover change maps based on moderate resolution imaging spectroradiometer (MODIS) and/or Landsat data sets (Hansen et al., 2013; Kim et al., 2014; Sexton et al., 2013; Townshend et al., 2012). Other products covering Europe only separate major tree species groups such as coniferous and broadleaf trees. Examples of these classifications include the forest high resolution layer (EEA, 2017a), the Pan-European forest type map (JRC, 2015) and the coordinated information on the environment (CORINE) land cover inventory (EEA, 2017b). An overview and comparison of various land cover products derived from EO data can be found in Pérez-Hoyos et al. (2012).

Studies analyzing species distribution at a more detailed level, e.g. with up to ten different species and often at the level of individual trees, are mainly based on optical EO data with high to very high spatial resolutions (VHR), such as IKONOS or WorldView-2 (WV2) (Carleer and Wolff, 2004; Fassnacht et al., 2017; Immitzer et al., 2012; Kim et al., 2011; Mora et al., 2010; Waser et al., 2014). Hence, the high potential of VHR data when applied within specific pilot studies and for relatively small areas has been confirmed. Detailed studies and examples that cover larger geographic extents, however, are still missing (Fassnacht et al., 2016).

The use of VHR data is often limited by high data costs. Consequently, most applications that cover large areas have focused on the use of cloud-free mosaics based on freely available data from the Landsat family which are often produced using the Best-Available-Pixel (BAP) method (Griffiths et al., 2013; Hermosilla et al., 2015; White et al., 2014; Zhu et al., 2015). With the launch of the European Sentinel-2 satellites, data with higher spatial, spectral and temporal resolutions have become available, creating new opportunities for tree species separation at the stand level (Immitzer et al., 2016b).

A recent overview of the possibilities, advantages and limitations of different satellite sensor data and methods can be found in a review from Fassnacht et al. (2016). The authors found that (i) the selected approaches and/or data sets often do not permit application to larger areas, (ii) most existing studies cover only small areas (in particular those based on VHR data), and (iii) data from passive sensors in the optical domain have greater potential for tree species separation than those from active sensors. This last finding is particularly true in terms of tree species whose phenological characteristics change significantly

with changes in season, making acquisition and processing of multi-temporal imagery important. Gómez et al. (2016) concluded that depending on the temporal resolution of the data used, both inter-annual changes and intra-annual dynamics (e.g. phenological development) can be detected using data from multiple time points. Recent examples of using multi-temporal Landsat data for classification include a land cover map of Germany provided by Mack et al. (2017) and the tree species and basal area maps of northern New York and Vermont produced by Gudex-Cross et al. (2017).

To improve land cover maps, some research groups have investigated the possibility of combining satellite data with different spatial resolutions. Well-known examples in forestry are studies that have combined data sets from Landsat and AVHRR (Fries et al., 1998) or Landsat and MODIS (Hansen et al., 2000). Other studies have derived continuous variables such as percent forest cover by combining Landsat and AVHRR (Iverson et al., 1989; Zhu and Evans, 1994). More recent studies have combined Landsat data with data sets of higher spatial resolutions such as IKONOS (Metzler and Sader, 2005) or GeoEye-1 data (Donmez et al., 2015). While most studies of this kind have focused on one general forest class, Metzler and Sader (2005) estimated the percentage cover of softwoods and hardwoods separately.

Techniques such as multiple regression (Iverson et al., 1989; Metzler and Sader, 2005; Zhu and Evans, 1994) or decision tree-based approaches (Donmez et al., 2015; Hansen et al., 2000; Thompson et al., 2015) can be used to create images of continuous variables, such as percentage of a given tree species. In recent years, the Random Forest algorithm has become popular for modeling continuous forest attributes based on EO data (Immitzer et al., 2016b; Mutanga et al., 2012; Stepper et al., 2017; Thompson et al., 2015; White et al., 2015). The key advantages of this non-parametric technique are that it requires relatively few assumptions about the structure of the data set, delivers information about the importance of the individual input data, provides an internal bootstrapping method for independent validation and utilizes a relatively fast and robust modeling framework.

Combining VHR data with freely available Landsat-type data has the potential for providing coverage of a larger spatial area along with the advantages of the detailed information data of high spectral resolution provides. To the best of our knowledge, no studies have yet been published that combine satellite data sets with very high (< 5 m) and medium (30 m) spatial resolutions for continuous (fractional) mapping of individual tree species. This study presents such an approach for estimating the fractional coverage of *spruce* and *pine* in 1 ha cells for the entire German state of Bavaria. This is realized with a two-step approach including: (i) classification of several VHR WV2 scenes distributed over the study area and covering only a part of the region of interest; and (ii) modeling the *spruce* and *pine* fractional cover derived from these VHR maps using spectral and temporal metrics derived from Landsat as explanatory variables. Finally, application of the calibrated models to the total area covered by the Landsat data yields maps covering the entire federal state of Bavaria.

The main objectives of the research presented here were to:

- Examine the suitability of Landsat time series data for upscaling tree species information derived from VHR imagery.
- Evaluate the added value of the two-step approach compared to a standard pixel-based classification of Landsat data.
- Quantify the trade-offs between the number of VHR scenes used (data acquisition and processing costs) and the quality of the maps generated.

For comparison, a pixel-based classification of Landsat time series data using the same reference data was applied. Both products were validated using an independent data set collected through visual interpretation of orthophotos.

Fig. 1. Workflow diagram of the two-step method used to generate fractional coverage maps for *spruce* and *pine*: (left – ‘First step’) creation of tree species maps using WV2 data distributed across the entire region of interest, (center – ‘Second step’) area-wide upscaling of tree species maps and subsequent production of final maps. Validation was done using 3780 1 ha cells of visually interpreted orthophotos. For comparison, Landsat data alone was also used to independently generate fractional coverage maps for *spruce* and *pine* (right – pixel-based approach).

## 2. Methods

To produce fractional coverage maps of *spruce* and *pine* for the entire state of Bavaria, a two-step approach was developed (Fig. 1). First, VHR ‘reference’ land cover maps were produced at 2 m spatial resolution using a supervised object-based approach performed on 47 WV2 scenes. The WV2 scenes were distributed across Bavaria, and cover roughly 20% of the total land area in the state. In a second step, the VHR land cover maps were used as reference information to upscale to the entire federal state of Bavaria. This was done using RF modeling to create classes for *spruce* (primarily European spruce, *Picea abies* (L.) H. Karst.), *pine* (primarily Scots pine, *Pinus sylvestris* L.) and *others* (all other tree species and non-forest land cover classes). The aggregated VHR tree species maps combined with data obtained from a cloud-free Landsat time series mosaic were used as reference data to create explanatory variables for use in a subsequent modeling step. To remove data gaps due to clouds and cloud shadows, smoothed and gap-filled Landsat time series data (Vuolo et al., 2017) were used. This also avoids the need for separate modeling of data derived from each Landsat acquisition path.

To assess the accuracy of the two-step approach, the three fractional coverages generated by the model were subsequently verified and validated using 3780 1 ha cells of visually interpreted orthophoto samples. We also assessed the impact of using fewer WV2 scenes on the accuracy of the models generated. In addition, a ‘classical’ (pixel-based)

classification of Landsat data was performed to compare the proposed approach against a simpler procedure.

The statistical software R 3.0.1 (R Core Team, 2014) and the packages *caret* (Kuhn et al., 2014), *matrixStats* (Bengtsson, 2014), *raster* (Hijmans, 2014) and *randomForest* (Liaw and Wiener, 2002) were used for the modeling step.

### 2.1. Study site – the federal state of Bavaria, Germany

With an area of approximately 70,500 km<sup>2</sup>, Bavaria is the largest federal state in Germany. Around 37% of the land area is covered with forests. Growing conditions are quite diverse in Bavaria, with oceanic influences in the north-west, a (sub)boreal climate in the north-east and subalpine conditions in the south. The largest part of Bavaria is characterized by a subcontinental or intermediate climate. The dominant life zones are colline to submontane, with some montane areas in the east and the south. As a consequence, the potential natural forest community would be dominated by different Fagetum types accompanied by some Quercetum types in the north-east and Piceetum types in the east and south (Walentowski et al., 2001). The actual forests have an average timber volume of 400 m<sup>3</sup>/ha and are dominated by Norway spruce (41.8%), and Scots pine (17.1%) interspersed with largely naturally established stands of European beech (13.9%) (Klemmt et al., 2014). Due to climate change, many spruce and pine forests are highly

**Fig. 2.** Color-infrared composites of the WorldView-2 scenes (bands 7,5,3) used as input data sets in modeling fractional coverage of *spruce* and *pine* for the entire state of Bavaria. (left); Example of a gap-filled and smoothed Landsat data mosaic (bands: 4,3,2) for August 2013 (right).

stressed, leading to increasing biotic and abiotic risks, in particular in areas where these species are planted outside their natural ranges (Kölling et al., 2009a; StMELF, 2013). Therefore, forest management activities are necessary to generate better-adapted stands with a mixture of tree species that is more resilient to changing climate conditions (Kölling et al., 2009a).

## 2.2. Data sets

### 2.2.1. WorldView-2 data

Forty-seven WV2 scenes (2 m pixel size) were used in this analysis. Scene selection was done to ensure representation of the forest ecoregions of Bavaria (Walentowski et al., 2001) and the availability of forest inventory data from the Bavarian state forest enterprise (BaySF) for these areas. To limit data costs, archived data were selected when possible, and new acquisitions of scenes were only requested when no usable archive data was available. The distribution of the WV2 scenes used is shown in Fig. 2, and detailed information about the scenes is found in Table S1 (Supplementary materials).

All WV2 data were pre-processed at the German Aerospace Center (DLR) using the automatic processing chain CATENA (Krauß et al., 2013; Reinartz, 2010), which includes orthorectification (Müller et al., 2005) and atmospheric & topographic correction (ATCOR) (Richter et al., 2006).

### 2.2.2. Landsat time series data

To model the fractional coverage of *spruce* and *pine*, a smoothed and gap-filled Landsat (LS) time series data set of images acquired in 2013 was used. Details about the process by which this data set was produced can be found in Vuolo et al. (2017). The approach yields a data set of bi-monthly cloud-free Bottom of Atmosphere (BoA) reflectance in the six Landsat spectral bands. An illustration of a data set for the second half of August 2013 is shown in Fig. 2. An example showing both raw and processed data can be found in Vuolo (2016).

Compared to the original Landsat scenes, the main advantage of smoothed and gap-filled Landsat time series data are:

- (i) A higher number of cloud-free observations per year (24

observations per pixel and year), equally distributed over the entire time period, and hence, covering all seasons.

- (ii) Spatially homogenous data over a large spatial extent.

In addition to the reflectance values in six spectral channels, several metrics derived from normalized difference vegetation index (NDVI, (Rouse et al., 1974)) images produced from the time series data were included in the analyses. These include:

- two NDVI values for each month (bi-monthly data),
- mean annual NDVI value,
- difference between average summer and winter NDVI values (amplitude).

### 2.3. Classification of WorldView-2 data and generation of reference fractional coverage information

An object-based approach using both spectral and textural information was used to classify each individual WV2 scene. Depending on the image location, landscape and species mixture represented in the reference data, up to 12 different land cover classes per scene were created (Fig. 3).

For image segmentation, eCognition Developer 8 was used. The parameters were fine-tuned for each scene to ensure that homogenous forest stands or tree groups were obtained and to avoid segmentation of individual tree crowns. Reference information based on inventory data as well as on visual interpretation of orthophotos and stereo aerial images was manually assigned to the segments.

For each segment, statistical values (mean, standard deviation, percentiles) for each of the eight spectral bands of the WV2 data and additional texture layers were produced (Table 1). The texture layers were derived from the red and near infrared bands and the NDVI image using a discrete stationary wavelet transformation (coiflets-family: coif1) similar to that used by Einzmann et al. (2017). More details about the wavelet transformation can be found in Toscani et al. (2013) and Immitzer et al. (2014).

The reference data sampling focused on the two target classes *spruce* and *pine*, with additional classes representing other forest and non-

**Fig. 3.** Preparation of the detailed WorldView-2 classification results and transfer of these results to the final 1 ha cells to be used as ‘reference’ data for the subsequent second step of the approach. The workflow includes thematic aggregation, shadow elimination and spatial aggregation.

forest classes where present. In regions with mixed stands of *spruce* and *pine*, a mixed class was also assigned. The reference data set creation was based on forest inventory data and color infrared (CIR) orthophoto interpretation. Approximately 850 training samples were generated for each scene.

This reference data was then used to perform a supervised classification using Breiman’s (2001) Random Forest (RF) algorithm. The parameter *mtry* was set to the square root of available input variables (default) and the *ntree* parameter to 1000. Detailed information about this ensemble learning algorithm and its advantages, such as the integrated bootstrapping that provides relatively unbiased ‘out-of-bag’ (OOB) results, can be found in the literature (Breiman, 2001; Hastie et al., 2009; Immitzer et al., 2012; Pal, 2005).

To optimize the classification output, a recursive feature selection process (Guyon et al., 2002) using the importance information obtained from RF was applied. The classification procedure with feature selection is described in detail in Immitzer et al. (2015) and Schultz et al. (2015).

After classification, both thematic and a spatial aggregation were carried out (Fig. 3). First, all classes except *spruce*, *pine*, *mixed spruce and pine*, *shadow* and *clouds* were combined to create one class labeled *others*. Neighboring polygons of the same classes were then dissolved, and ‘shadow’ polygons were merged with the neighboring polygon with which they shared the longest border. The classification results obtained were visually compared to orthophotos, and corrected when necessary to prevent classification errors from propagating to the final

modeling product. Non-interpretable areas and the *clouds* class were set to ‘no data’ (NA) and excluded from the procedures that followed. For the subsequent spatial aggregation, a Bavaria-wide raster with a pixel size of 1 ha was produced, and, in the areas covered by the WV2 scenes, fractional coverages (in %) for each of three classes *pine*, *spruce*, and *others* were calculated for each 1 ha cell. The *mixed spruce and pine* class was allocated equally to the two main classes. Cells including NA areas and those not fully covered by the WV2 classification results were discarded.

#### 2.4. Upscaling of the classification results to area-wide maps

After creation of the reference data set, the second part of the method involved developing models for mapping fractional coverages of *spruce* and *pine* for the entire forested area of Bavaria. For the Landsat data sets, all pixels were disaggregated to 10 m spatial resolution using a nearest neighbor resampling algorithm aligned to the 1 ha grid of cells from the fractional coverage map. The aligned 10 m pixels were then summarized in terms of mean, standard deviation and percentiles to characterize the distribution of reflectance values and the NDVI values within each 1 ha cell (Table 2).

RF regression models were then trained for each of the three classes *spruce*, *pine* and *others* using the aggregated information described in the previous section. Explanatory variables were obtained from available Landsat time series data, including both spectral reflectance values and NDVI. From those variables, additional features such as amplitude and

**Table 1**  
Explanatory variables for the classification models used in the first step of the approach.

EO input data	No. of layers	Metrics calculated for each polygon	No. of explanatory variables
WorldView-2 spectral bands	8	Mean, standard deviation, percentiles: minimum, 5th, 10th, 25th, median, 75th, 90th, 95th, maximum	88
Normalized difference vegetation index (NDVI)	1	Mean, standard deviation, percentiles: minimum, 5th, 10th, 25th, median, 75th, 90th, 95th, maximum	11
Wavelet coiflet1 texture	12	Mean, standard deviation, percentiles: minimum, 5th, 10th, 25th, Median, 75th, 90th, 95th, maximum	132

**Table 2**

Explanatory variables for the regression models created in the second step of the approach.

EO input data	No. of layers	Metrics calculated for each 1 ha cell	No. of explanatory variables
Landsat Reflectance June 2013	6	Mean, standard deviation, percentiles: minimum, 25th, median, 75th, maximum	42
Landsat Reflectance Aug 2013	6	Mean, standard deviation, percentiles: minimum, 25th, median, 75th, maximum	42
Normalized difference vegetation index (NDVI) bi-monthly time series 2013	24	Mean, standard deviation	48
Normalized difference vegetation index (NDVI) bi-monthly time series 2013	24	Amplitude and mean value March to August, mean of the year	3

mean values of the vegetation period were extracted. For the reflectance values, only data sets from the end of June 2013 and the end of August 2013 were used. A comprehensive list of all explanatory variables is provided in Table 2. RF regression models were used, as they have a number of advantages that are particularly relevant for this application. These advantages include a reduced risk of overfitting the model, determination of variable importance, and the ability to handle different data types (Gómez et al., 2016; Hastie et al., 2009; Immitzer et al., 2016a). Similar to the classification approach, the RF regression includes internal bootstrapping, and provides relatively unbiased ‘out-of-bag’ (OOB) results.

Within each WV2 classification result converted to class-specific proportions, 5000 1 ha cells were extracted as training samples. Training points were chosen such that all cells having the highest proportion (top 2%) of the classes *spruce* and *pine* were sampled, with the remaining points chosen randomly. RF models were generated separately for each of the three target classes *spruce*, *pine*, and *others*. First, an RF model was built using all available Landsat metrics. Based on the feature importance information obtained from the RF model, the 100 most important explanatory variables were chosen to build a new model. The default values for *ntree* (500 trees) and *mtry* (third of the total number of input features) were used in model creation. Next, the models for each of the three classes were separately applied to the entire study area. Afterwards, the three maps were combined and, if necessary, rescaled so that the classes summed to 100% for each 1 ha cell. Areas outside of forests were manually set to 100% *others* using the vectorized forest information (forest mask) from the Authoritative topographic-Cartographic Information System (ATKIS) (AdV, 2015).

## 2.5. Reduction of the number of WorldView-2 scenes

The use of a large number of VHR scenes entails high costs for data provision and analysis. To better understand the cost-benefit relationship between accuracy and number of WV2 scenes used, the input scenes were reduced iteratively from the original 47 (total number of available WV2 scenes) to 1, using a greedy algorithm. In each step, the WV2 scene which led to the smallest increase in the average distance of empty cells to the sampled training cells of the respective nearest scene was removed.

Greedy algorithms have the advantage of being fast and easy to compute but do not necessarily lead to optimal solutions. Also, content and data quality of the individual WV2 scenes are not considered in this approach, which is depicted in Fig. 4.

## 2.6. Comparison to pixel-based classification of Landsat data

To demonstrate and quantify the added value of the two-step approach, a standard pixel-based classification of the LS data set was performed for comparison. Again in this case, an RF classification (*ntree* = 1000, *mtry* = square root of the number of input features) was done using the same reference data which were used to classify the WV2 scenes, excluding the *mixed spruce and pine* class. For each reference polygon, the most central (30 m) LS pixel was used. Eight

classes were distinguished: *spruce*, *pine*, *other coniferous trees*, *broadleaf trees*, *non-forest vegetation*, *water*, *natural areas without vegetation* and *sealed areas*. In total, the number of reference pixels used for the classification was 4870 for *spruce*, 2080 for *pine*, 2821 for *other coniferous trees*, 5805 for *broadleaf trees* and 8031 for *non-forest vegetation*, 3190 for *water*, 2369 for *natural areas without vegetation* and 8251 for *sealed areas*. The same 37 Landsat metrics used in the upscaling done in the two-step approach (Table 2) were used for the pixel-based RF classification. The model was applied to the entire study site. Again, all classes except *spruce* and *pine* were combined to create a class labeled *others*. The pixel-based classification results were subsequently aggregated to the 1 ha cells in the same way described above, to create a second set of fractional coverages for each of the three classes.

## 2.7. Validation using independent samples from orthophotos

For independent validation, a regular raster grid of the entire state of Bavaria with 2.5 km × 2.5 km cell size was produced. For each of the 3780 raster points inside the forest mask, the corresponding 1 ha cell was assigned a class based on visual interpretation of CIR orthophotos conducted by experienced photo-interpreters. The fractional coverages of the three classes *spruce*, *pine* and *others* were assessed in 5% steps. The resulting independent validation data set is shown in Fig. 5.

To assess the relative precision and accuracy of the two models (i.e. the two-step approach vs. the pixel-based Landsat classification), the root mean squared error (RMSE), the bias and the coefficient of determination ( $R^2$ ) were calculated for each class (*spruce*, *pine*, *others*) independently (see, for example Immitzer et al., 2016a for formulas).

## 3. Results

### 3.1. Land cover maps based on WV2 scenes

The median OOB overall accuracy (OA) for the 47 WV2 scenes was 93.8% (ranging from 87.6 to 97.4%), with some variation in class-specific results (Fig. 6). Note that classes which were only present in some WV2 scenes were aggregated to more general class groups. For example, *European larch*, *Douglas fir* and *white fir* were combined in Fig. 6 to create the class *other coniferous tree species* (post-classification grouping).

The producer's accuracies (PA) for *spruce* ranged between 76.1 and 98.4% (median 88.0%), and those for *pine* between 30.4 and 100% (median 85.9%). The user's accuracy (UA) ranged between 70.6 and 95.9% (median 88.2%) for *spruce* and 58.3 and 100% (median 84.7%) for *pine*. The values for the other forest classes showed similar variation. The non-forest classes achieved higher accuracies with lower variability amongst the 47 WV2 scenes (Fig. 6).

As expected, image quality (acquisition date and acquisition parameters) determined the usability of the WV2 data for tree species separation. Data from scenes acquired in summer months (June to August) and acquisitions with near-nadir view angles showed the highest suitability and achieved the highest accuracies (Supplementary materials Table S1). For good class-specific performance, an adequate

**Fig. 4.** Visualization of the iterative reduction in the number of WV2 scene, in which the decision of which scene to eliminate next was based on the average distance between the 1 ha cells and the next nearest training cell: all 47 scenes (left), 15 scenes (center), last remaining scene (right). Remaining scenes are depicted in green. The grey-scale values represent the distance which ranges from 0 km (white) to 226 km (black). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

number of high-quality reference data was necessary.

The confusion matrix based on the OOB results of all reference data is shown in Table 3. To generate this confusion matrix, the results of the 47 individual WV2 scenes were again combined. The class *mixed spruce and pine* had the lowest class-specific accuracy, as this class was mainly confused with the (pure) *spruce* and *pine* classes. Next to the mixed class, the two other forest classes *coniferous tree species* and *broadleaf tree species* showed the highest confusion with the two target classes *spruce* and *pine*.

A visual check of the classified images sometimes revealed differences in model performance and map accuracy. Apparent misclassifications of the main classes *spruce* and *pine* were manually corrected to avoid negative impacts on the final maps. The average

resulting change in the classification was around 2.5% of the classified area (roughly one working day per scene). For some scenes, a greater amount of effort was necessary, as scene quality and/or reference data were sub-optimal (Supplementary materials Table S1).

For the second step, 5000 samples (1 ha cells) from each spatially and thematically aggregated WV2 classification result were used. The data distribution for each of the three classes is shown in Fig. 7.

### 3.2. Bavarian-wide spruce and pine maps

The RF regression models based on all 47 WV2 scenes, using only the most important Landsat-based predictor variables, explained 79.8% of the variance for *spruce*, 77.0% for *pine* and 87.9% for the class *others*

**Fig. 5.** Independent validation data set (regular 2.5 km × 2.5 km raster) produced by visual interpretation of the corresponding 1 ha cell using orthophotos. The colors represent the dominant class: green triangles indicate spruce, blue circles represent pine, red squares illustrate others and grey diamonds, non-forest (only areas inside the forest mask were interpreted). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

**Fig. 6.** Distribution of the producer's, user's and overall accuracies based on the OOB model results of the 47 WorldView-2 scene classifications. Classes which were used only for some scenes were aggregated to more general class groups. (Abbreviations: S/P mixed: mixed spruce and pine stands, Conif: other coniferous tree species, Broad: broadleaf tree species, Veg: non forest vegetation, Veg free: natural areas without vegetation).

(OOB results). The most important variables for the *spruce* modeling were the spectral reflectance values from the two Landsat data sets (Bands 1, 4 and 3) and NDVI values from all seasons. Similar features were important for the *pine* models, with the main difference being increased importance of the NDVI metrics.

The results of the two-step mapping are presented in Fig. 8. The maps show fractional coverages of *spruce* and *pine* from the WV2 classifications (top) and the Landsat-based upscaling (bottom), at a spatial resolution of 1 ha. For > 90% of the 1 ha cells the sum of the fractional coverage results of the three classes ranged between 98 and 102%. For the final maps, all cells were rescaled to yield 100% in total.

The results of the independent validation of the two-step approach and the direct (pixel-based) classification of Landsat data are shown in Fig. 9. The  $R^2$  values for *spruce* and *pine* were 0.72 and 0.75, respectively. The RMSE was 12.1% for *pine* and 14.2% for *spruce*. For all three classes, bias was close to zero. With an  $R^2$  value of 0.82, the highest correlation with the two-step approach was found for the class *others*, which in this case represents only the other forest classes, as the

validation was applied only in forested areas.

The results for the pixel-based classification of the LS data (OOB results are given in the Supplementary materials Table S2) were considerably worse (Fig. 9, center row). For all three classes, significantly lower  $R^2$  values, higher RMSE and higher bias values were observed. The bottom row of Fig. 9 illustrates the model deviations from the independent validation data. For example, in the case of the two-step approach for *spruce*, approximately 75% of the 1 ha cells are modeled within the error margin of  $\pm 15\%$ , while only 67% of the cells were correctly modeled using the pixel-based approach. The bar charts in Fig. 10 further summarize the strong improvement ( $R^2$ , RMSE and bias) obtained with the two-step mapping approach.

### 3.3. Reduction of WV2 scenes

To test the influence of the number of inputs, the number of WV2 scenes used was reduced in a step-wise process. With a decreasing number of scenes, the  $R^2$  decreased and the RMSE increased (Fig. 11).

**Table 3**

Fig. 7. Histograms of the reference data for the second step for the three Classes *spruce* (left), *pine* (center) and *others* (right). Data were obtained from the WV2 classification results.

However, the modeling accuracy decreased only slightly when the number of scenes used was reduced from the original 47 to 15 WV2 scenes. Only below this point did further reduction of the number of WV2 scenes lead to significant decreases in model performance. A relatively close relationship is seen between the modeling error (e.g. RMSE) and the average distance of (empty) cells to the location of the nearest WV2 scene (bottom of graphs), demonstrating the strong impact of (spatially) well distributed and dense training samples (here coverage with very high resolution data) on modeling accuracy.

#### 4. Discussion

##### 4.1. Model approach

Compared to a conceptually and computationally simpler pixel-based classification, our two-step method achieved considerable improvement in accuracy using the same basic reference data. The likely source of the increase in model accuracy is the fact that the two-step process allowed substantially more training points to be collected than is possible using a simple pixel-based classification. By first classifying WV2 data; we obtained a larger amount of reference data, likely better capturing the spectral differences between the mapped tree species. Peculiarities in spectral and temporal signatures may, for example, result from differences in stand management and/or growing conditions at a particular site. In addition, the large amount of reference data can reduce the influence of possible misclassification introduced in the first step.

The presented two-step method for mapping fractional coverage of tree species gave good results, with 75% (*spruce*) to 84% (*pine*) of the validation samples being modeled within the assumed uncertainty of  $\pm 15\%$  of the reference samples. The achieved  $R^2$  values based on the independent validation samples were only slightly lower than the OOB results for the three RF regression models, with similar trends and patterns. This confirms the validity of OOB statistics for assessing RF models mentioned in other studies (Hastie et al., 2009; Immitzer et al., 2016a).

A completely independent validation based on orthophoto interpretation using a regular grid covering the entire study site was performed to assess model accuracies. The disadvantage of this approach is that spatial shifts (or layover effects) between the orthophotos and the map products could potentially have negative impacts on validation accuracy. Nevertheless, we obtained satisfactory results. Our study achieved  $R^2$  values for the three target classes ranging from 0.72 to 0.82 that are notably higher than those found in a similar study by Metzler and Sader (2005). They reported  $R^2$  values of around 0.66 for the two classes when upscaling soft- and hardwood coverages obtained from IKONOS data to (multi-temporal) Landsat data. However, their analysis was carried out in a different geographic area with different target

variables, thus limiting the value of a direct comparison. Other studies using similar approaches for modeling forest cover also obtained similar  $R^2$  values of around 0.80 (Dommez et al., 2015; Iverson et al., 1989; Sexton et al., 2013).

The mapped spatial distribution of *spruce* and *pine* is similar to those produced by the European Forest Institute (EFI) (not shown) based on kriging of inventory data (Brus et al., 2012). However, the maps produced in our study have two main advantages: (i) they provide a higher spatial resolution, and (ii) the artifacts which sometimes appear in the EFI maps for species with rare(r) occurrences (e.g. strong overestimation around single inventory plots) are absent.

Compared to the official figures for *spruce* and *pine* acreages provided by the Bavarian State Institute of Forestry, we found distinct differences. According to the official data derived from National Forest Inventory (NFI) plots, *spruce* covers 41.8% of the forested area of Bavaria, and *pine* 17.1% (Klemmt et al., 2014). From our data, however, we calculated only 30.1% for *spruce* and 14.9% for *pine*. We believe that the differences mainly result from diverging definitions of ‘coverage’. For example, in our approach, we map the percentage crown coverage in each 1 ha cell, whereas in the NFI a forest gap is counted as *spruce* if it is located inside a *spruce* stand.

##### 4.2. Considerations regarding the VHR input data

The classification of the WV2 data achieved very good results overall. This is in line with several other studies that have demonstrated the great potential of WV2 data for detailed land cover mapping, including forest (Fassnacht et al., 2017; Immitzer et al., 2012; Karlson et al., 2016; Omer et al., 2015; Waser et al., 2014).

The main drawback of WV2 data is its relatively high cost. Depending on the number of occurring tree species in a given study area, less expensive data with fewer spectral bands (see, for example Waser et al., 2011 for use of airborne imagery) could possibly be equally suitable for tree species classification (Immitzer et al., 2012). As discussed, the sole purpose of the use of WV2 data in our study was to expand the amount of detailed data available for training of RF regression models. This could potentially also be achieved by making use of other pre-existing high resolution maps. Fassnacht et al. (2016) for example highlighted the fact that most of the tree species classification studies considered in their review paper were data-driven and covered only very small test sites with limited operational implementation opportunity. Hence, maps resulting from such small-scale studies could be interesting input data sets for use in upscaling approaches such as the method presented here. Using pre-existing classification results (even those from different sensors) could further reduce data costs and, therefore, be a cost-efficient tool for producing large-scale tree species maps. Obviously, the quality of the VHR tree species classification is very important for the overall modeling approach. Any

**Fig. 8.** Intermediate and final results of the two-step approach for spruce (left) and pine (right): aggregated WorldView-2 classifications (top); results of the large scale mapping using Landsat time series to scale the WorldView-2 classifications up to the entire state of Bavaria (bottom).

misclassification will negatively influence model accuracy in the second step.

As expected, the date of the image collection and the acquisition parameters had significant impacts on the resulting classification accuracy. We used 47 WV2 scenes with off-nadir angles ranging from 2 to 25°. These images were acquired between the end of April and the end of September. The scenes acquired in April or the beginning of May were sub-optimal for tree species differentiation, due to the leafless state of deciduous trees. In scenes covering mountainous areas, even images from late May were not always adequate, since the broadleaf trees in the valley had already developed leaves, whereas in the leaves were still absent at higher elevations. For tree species classification in Central Europe, we suggest using images acquired between mid-June and the end of August. This proposed acquisition period also minimizes

the potential for negative impacts from illumination effects, like the length of cast shadows.

Another important factor influencing the quality of the classifications was variation in off-nadir angle and viewing geometry. The images used in this analysis were acquired with different off-nadir angles. The scenes with angles up to 15° were generally satisfactory. However, with higher view angles, especially those > 20°, we observed some noticeable distortions in the images. This effect was most pronounced in scenes with hilly terrain.

In order to assess the impact of the number of input scenes versus mapping accuracy, we analyzed a higher number of WV2 scenes than was thought necessary for an optimal cost versus accuracy trade-off. By experimenting with using fewer scenes, we demonstrated that a far smaller number of scenes are sufficient if these scenes are well

**Fig. 9.** Validation results: results of the two-step approach (x-axis) plotted against the independent validation data set produced using orthophoto interpretation (1st row), the same comparison for the direct pixel-based classification (2nd row); (for better visualization of the data, some random variation was added to the validation estimations using the jitter function), Cumulative distribution functions of the differences between the model results and the validation data for the two model approaches (vertical lines at  $\pm 15\%$  were added to display the probable uncertainty margin of the visual reference estimation) (3rd row).

distributed over the study area and cover the various land cover and forest types present in the study area. In this particular case, we observed nearly no decrease in model performance as the number of WV2 scenes used as inputs was reduced from 47 to 15. Only below that number, did errors begin to increase significantly, likely because critical training samples were no longer available. The training data obtained from these 15 scenes covers roughly 1% of Bavaria, as only 5000 cells from each scene were used for the modeling approach (covering a total land area of 750 km<sup>2</sup>).

#### 4.3. Suitability of Landsat time series data to generate explanatory variables

Ten Landsat scenes from four paths (192 to 195) are necessary to cover the entire land area of Bavaria. Getting cloud-free data for such a large area (acquired within a short time interval and close to key phenological dates) is a challenge. Difficulties increase if multi-temporal data are necessary to be able to distinguish between spectrally similar classes (Beck et al., 2006; Ju and Roy, 2008). To minimize the impacts of clouds and acquisition time, we first tried to identify and process suitable data for two dates from each path. Modeling was done

**Fig. 10.** Comparison of the validation results for the three classes *spruce*, *pine* and *others* obtained using the two methods: the two-step approach (black) and the pixel-based classification (grey):  $R^2$  values (left), RMSE values (center), and bias values(right).

for each path separately (Immitzer et al., 2015). This requires the availability of a sufficient amount of WV2 data per path. After modeling, some post-processing is required to mosaic the mapping results from the four paths together to create area-wide maps. To avoid problems related to the strip-wise data processing, we used in this study gap-filled time series data (Vuolo et al., 2017). The gap-filling process involves the creation of wall-to-wall homogeneous mosaics in the original Landsat spectral bands at bi-monthly temporal resolution (Fig. 2). Hence, the entire study region can be processed in one step. For the three classes *spruce*, *pine* and *others* we obtained nearly identical performance:  $R^2$  values for *spruce*, *pine* and *others* were 0.72, 0.75 and 0.82, compared to 0.74, 0.79 and 0.83 when processing the data strip-by-strip (Immitzer et al., 2015). Similar results were found for the RMSE, while the bias was reduced by using the gap-filled data.

Using smoothed and gap-filled Landsat data (Vuolo et al., 2017) thus, simplifies processing and offers a number of further advantages: (i) any number of cloud-free images from one specific vegetation period can be used, and (ii) fewer reference data are necessary, as larger areas are covered than in the original Landsat scenes/paths. Both aspects deserve more research. In particular, we did not utilize the full time series of spectral data, but instead used data from only two time steps (Table 2). Using additional data could be useful, especially in efforts to map a larger number of tree species.

## 5. Conclusion

The two-step method developed in this research provides a good framework for producing high quality tree species maps for large areas. The generated mapping results are important for forest monitoring and management activities. Specifically, the spruce and pine maps generated in this study will be combined with risk maps by the Bavarian State Institute of Forestry to be used in locating hot spots where forest conversion activities should be prioritized. The fractional coverage maps at a resolution of 1 ha are potentially useful for several other applications such as landscape modeling or monitoring tasks.

The method developed here combines large-area Landsat mosaics with very high resolution (VHR) WorldView-2 (WV2) data covering only a relatively small part of the region of interest in a computationally efficient way. The use of WV2 data permits expansion of the reference data later available to train the RF models based on Landsat metrics. The use of Landsat data for the final mapping considerably reduces the costs associated with the acquisition and processing of commercial VHR data over large areas.

In the present study, the approach was solely applied to map spruce and pine. Obviously, application to other species is possible. The method also permits the use of pre-existing (high resolution) maps as inputs. To achieve acceptable accuracies, it is important that the full variation in landscape types within the study area is well covered by the VHR imagery or similar input data. In Bavaria, which has a very

**Fig. 11.** Validation results for RF-models based on decreasing numbers of WorldView-2 scenes (stepwise reduction of input data) for the three classes *spruce*, *pine* and *others*: (left)  $R^2$  values, (center) RMSE values, and (right) Bias values. At the bottom of each graph, the average minimum distance (MinDist) between (empty) 1 ha cells to the nearest WorldView-2 image used is shown.

heterogeneous landscape ranging from the Alps to lowlands, we found that the very high resolution reference data should cover roughly 1% of the total area in order to achieve 10–15% accuracy (RMSE) for mapping fractional coverage of spruce and pine. For our data set, less comprehensive coverage significantly increased the modeling errors, as local variation in spectral signatures was no longer captured.

The approach presented here is likely transferable to many other remote sensing applications, and could potentially also work with other VHR data (e.g., orthophotos, UAV, aerial airborne hyperspectral data) combined with other decametric inputs such as Sentinel-2 instead of Landsat data.

## Acknowledgments

The work has been partly supported by grants provided within the research project E52 TreIdent, funded through the Bavarian State Ministry of Food, Agriculture and Forestry. This support is greatly appreciated. We would also like to thank the Bavarian State Forest Enterprise for providing field inventory data; Gerald Lindner, Gerhard Mocza, Wai-Tim Ng, Valentin Pesendorfer, Martin Siklar and Franz Suppan for supporting the WV2 classification; Matteo Mattiuzzi for assisting data preparation and modeling; and Anne Reichmuth and the DLR team for their help with WV2 data processing. The authors also gratefully acknowledge the efforts of four anonymous reviewers who offered valuable recommendations, and Laura Carlson for language editing.
